Abstract

Mathematics anxiety is a feeling of tension about mathematics, and understanding how it relates to achievement helps teachers in primary and lower secondary schools support their students. Using an automated workflow in which every extracted number was verified against the full text, 10 open-access studies ($N = 5389$) were pooled with a random-effects model. The pooled effect was $r = -.34$, 95% CI $[-.49, -.17]$, with $I^2 = 96.9\%$. Higher mathematics anxiety was generally linked with lower achievement, but the size of the link varied widely, so teachers should treat it as a correlation rather than a proven cause.

Keywords: meta-analysis, mathematics anxiety, mathematics achievement, primary education, lower secondary education, correlation

The Relationship Between Mathematics Anxiety and Mathematics Achievement in Primary and Lower Secondary Students: A Meta-Analysis

Mathematics is taught to all children in primary and lower secondary schools, yet many students feel tense or worried when they work on it. Such feelings are usually called mathematics anxiety. In school, mathematics anxiety is typically measured by asking students to rate how uneasy they feel in situations that involve numbers, lessons and tests. Because teachers meet students of many ages and backgrounds, they need to know whether students' anxiety goes together with how well they do in mathematics.

Many studies have examined this question in different countries and school levels. The included studies surveyed students from the early primary grades to the lower secondary grades and used a variety of anxiety scales, tests and school grades (Beyaztaş & Bostancı, 2023; Mutlu, 2019; Ruijia et al., 2022; Sánchez-Pérez et al., 2021). Some of them reported a clear negative association between anxiety and achievement (Beyaztaş & Bostancı, 2023; Mutlu, 2019; Ruijia et al., 2022), whereas others reported weaker associations (Carey et al., 2017; Reali et al., 2016) or even a small positive one (Peteros et al., 2025). These differences make it hard for a teacher or a school leader to judge how much weight the finding deserves.

A quantitative synthesis is useful in this situation. By converting each result into the same effect size, a meta-analysis can estimate the typical size of the association, show how much the results differ across studies, and ask whether the association looks different for younger and older students. Because the predictor and the outcome were measured at the same time in most studies, the synthesis describes association, not cause and effect.

The purpose of this meta-analysis was to estimate the overall correlation between mathematics anxiety and mathematics achievement among students in grades 1 to 9. Our research question was: how strong is the relationship between mathematics anxiety and mathematics achievement in primary and lower secondary students, and does this relationship differ across school levels?

Method

Literature Search

Searches were run on October 6, 2026 in two open bibliographic sources. OpenAlex was searched in the title and abstract fields with the query “(“math anxiety” OR “mathematics anxiety” OR “mathematical anxiety”) AND (achievement OR performance) AND (elementary OR primary OR “middle school” OR “junior high” OR “lower secondary” OR grade OR children OR pupils)”, restricted to open-access journal articles published in 2012 or later and classified in the Education or Developmental and Educational Psychology subfields. J-STAGE, the Japanese journal platform, was searched in the abstract field with the keywords “数学不安 学力”, “算数 不安 成績” (2012 or later) to include studies published in Japan.

Eligibility Criteria

Studies were eligible if they (a) sampled students in grades 1-9 (primary/elementary school and lower secondary/middle/junior high school, ages about 6-15); Exclude preschool-only, upper secondary-only, university, adult, and teacher/pre-service teacher samples; (b) examined mathematics anxiety measured by a questionnaire (predictor); (c) reported the correlation with mathematics achievement or performance measured by a test or grades; and (d) reported the sample size. Reviews, qualitative studies, single-case designs, and single-group pre-post designs were excluded.

Screening and Data Extraction

Screening and data extraction were automated. A large language model (claude-sonnet-5-5 (Claude Code, local)) rated each title and abstract against the eligibility criteria. Full texts (PDF) of the highest-rated records were retrieved and converted to plain text, and the model extracted study characteristics and summary statistics from them. Every extracted number was then checked by software against the full text, and a study was excluded from the synthesis if any extracted number could not be found verbatim. No human reviewer verified the screening or the extraction. When more than 10 studies qualified, the 10 with the highest screening ratings were retained.

Effect Sizes

Pearson correlations were transformed to Fisher's z for analysis, with sampling variance $1/(N - 3)$, and back-transformed to r for reporting.

Statistical Analysis

Effect sizes were pooled with a random-effects model in which the between-study variance (τ^2) was estimated with the DerSimonian–Laird method (DerSimonian & Laird, 1986). Confidence intervals and tests of the pooled effect used the Hartung–Knapp–Sidik–Jonkman (HKSJ) adjustment, which is recommended when the number of studies is small (Hartung & Knapp, 2001; IntHout et al., 2014). Heterogeneity was assessed with Q , I^2 (Higgins & Thompson, 2002), τ^2 , and a 95% prediction interval. Subgroup analyses by school level (elementary: grades 1–6; lower secondary: grades 7–9) were conducted when each level included at least two studies. Robustness was examined with leave-one-out analysis, and Egger's regression test (Egger et al., 1997) was planned only when at least 10 studies were available. Effect magnitudes were interpreted with conventional benchmarks (Cohen, 1988). Analyses followed standard formulas (Borenstein et al., 2009) implemented in open-source JavaScript code (<https://github.com/k518-2026/MetaAnalysisToWP>).

Results

Study Selection

The searches returned 200 records from OpenAlex (of 313 matching the query) and 0 from J-STAGE, for 200 unique records. Of the 193 records with abstracts that were screened, 76 were rated as potentially eligible. Full texts of 23 records were examined: 9 could not be retrieved or read, 4 did not meet the eligibility criteria, 0 did not report sufficient statistics, 0 contained extracted numbers that could not be verified in the text, and 0 yielded implausible values. In total, 10 studies were included in the meta-analysis.

Study Characteristics

Table 1 summarizes the country, grade, design, sample size, and effect size of each included study (Anbar et al., 2022; Balakonda, 2025; Beyaztaş & Bostancı, 2023; Carey et al., 2017; Mutlu, 2019; Peteros et al., 2025; Reali et al., 2016; Ruijia et al., 2022; Sánchez-Pérez et

al., 2021; Song et al., 2023). The studies comprised 5389 participants in total and were conducted in Turkey, Philippines, United Kingdom, Spain, Palestine, India, China, United States, Colombia. By school level, 6 studies sampled elementary (grades 1–6) students, 2 studies sampled lower secondary (grades 7–9) students, 2 studies sampled mixed grades students. Sample sizes ranged from 30 to 1720, and individual effect sizes ranged from $r = -.60$ to $r = .12$.

Table 1
Overview of the Included Studies

Study	Country	Grade	Design	<i>N</i>	<i>r</i> [95% CI]
Beyaztaş and Bostancı (2023)	Turkey	Grade 4	correlational (explanatory sequential mixed methods)	589	-.57 [-.62, -.51]
Peteros et al. (2025)	Philippines	Grade 8	descriptive correlational	612	.12 [.05, .20]
Mutlu (2019)	Turkey	Grade 3	correlational	288	-.60 [-.67, -.52]
Carey et al. (2017)	United Kingdom	Year 4 and Years 7-8	correlational (latent profile analysis)	1720	-.29 [-.33, -.25]
Sánchez-Pérez et al. (2021)	Spain	Grades 3-6	correlational (scale validation)	967	-.26 [-.32, -.20]
Anbar et al. (2022)	Palestine	Grades 3-4	correlational	230	-.25 [-.37, -.12]
Balakonda (2025)	India	Grade 9	correlational	30	-.39 [-.66, -.03]
Ruijia et al. (2022)	China	Grade 6	correlational	450	-.59 [-.64, -.52]
Song et al. (2023)	United States	Grades 3-6	correlational (path model)	207	-.28 [-.40, -.15]
Realí et al. (2016)	Colombia	Grades 3-6, 9 and 10	correlational	296	-.17 [-.28, -.06]

Note. CI = confidence interval. *r* = Pearson correlation. Grades and designs were extracted automatically from the full texts.

Table 2 lists the predictor and outcome measures used in each study.

Table 2
Predictors and Outcome Measures

Study	Predictor	Outcome
Beyaztaş and Bostancı (2023)	mathematics anxiety scale (total)	mathematics lesson report card grades
Peteros et al. (2025)	mathematics anxiety questionnaire	final grades in mathematics from school records

Study	Predictor	Outcome
Mutlu (2019)	math anxiety scale	mathematics achievement test
Carey et al. (2017)	math anxiety questionnaire	mathematics performance test (MaLT)
Sánchez-Pérez et al. (2021)	Scale for Early Mathematics Anxiety (SEMA), global score	final math grades reported by teachers
Anbar et al. (2022)	Scale for Early Math Anxiety (SEMA)	math achievement
Balakonda (2025)	Mathematics Anxiety Scale	Summative Assessment-1 marks
Ruijia et al. (2022)	math anxiety scale	math achievement
Song et al. (2023)	child-reported math anxiety	standardized math achievement test
Realí et al. (2016)	Abbreviated Math Anxiety Scale (AMAS)	math performance test

Note. Extracted and summarized automatically from the full texts.

Overall Effect

Figure 1 shows the forest plot. Each square marks the effect size of one study, with its size proportional to the study's weight, and each horizontal line marks the 95% confidence interval; the diamond at the bottom is the pooled estimate. 1 of the 10 studies had positive effect sizes, and the confidence intervals of 10 studies did not include zero. The study with the largest weight was Carey et al. (2017) (10.7%).

Figure 1

Forest Plot of Individual and Pooled Effect Sizes

Note. Squares show study effect sizes (size proportional to weight), lines show 95% confidence intervals, the diamond shows the pooled estimate, and the dashed line shows the prediction interval.

The random-effects model yielded a pooled effect of $r = -.34$, 95% CI $[-.49, -.17]$,

$t(9) = -4.32, p = .002$, which corresponds to a moderate effect by conventional benchmarks.

The fixed-effect estimate was $r = -.32$. Table 3 summarizes these estimates.

Heterogeneity

Heterogeneity was considerable, $Q(9) = 288.53, p < .001, I^2 = 96.9\%, \tau^2 = 0.063$. The 95% prediction interval ranged from $-.75$ to $.25$.

Subgroup and Sensitivity Analyses

For elementary (grades 1–6) samples, $r = -.44$, 95% CI $[-.61, -.24]$ ($k = 6$); for lower secondary (grades 7–9) samples, $r = -.11$, 95% CI $[-1.00, 1.00]$ ($k = 2$); for mixed grades samples, $r = -.24$, 95% CI $[-.77, .48]$ ($k = 2$). The difference between school levels was not statistically significant, $Q(2) = 4.84, p = .089$. Leave-one-out estimates ranged from $-.39$ to $-.31$. Egger's test did not indicate funnel plot asymmetry (intercept = $-1.96, p = .680$). The subgroup estimates are also shown in Table 3.

Table 3

Results of the Meta-Analysis

Model	k	N	r	95% CI	p	I^2 (%)	τ^2
Random effects (HKSJ)	10	5389	$-.34$	$[-.49, -.17]$	.002	96.9	0.063
Fixed effect	10	5389	$-.32$	$[-.34, -.29]$	< .001	—	—
elementary (grades 1–6)	6	2731	$-.44$	$[-.61, -.24]$	.003	95.4	0.049
lower secondary (grades 7–9)	2	642	$-.11$	$[-1.00, 1.00]$	.750	86.5	0.124
mixed grades	2	2016	$-.24$	$[-.77, .48]$	.151	73.5	0.006

Note. k = number of studies. HKSJ = Hartung–Knapp–Sidik–Jonkman confidence interval. 95% prediction interval $[-.75, .25]$.

Discussion

The random-effects model gave a pooled correlation of $r = -.34$, 95% CI $[-.49, -.17]$, which is a moderate negative association by conventional benchmarks (Table 3). In the included studies, students who reported more mathematics anxiety tended to have lower mathematics achievement. Nine of the ten studies showed a negative correlation, and the exception was a study of eighth graders with a weak positive correlation (Peteros et al., 2025). The largest negative correlations came from studies of single grades in Turkey and China (Beyaztaş & Bostancı, 2023; Mutlu, 2019; Ruijia et al., 2022), while the largest sample showed a smaller correlation (Carey et al., 2017) (Figure 1).

The results varied widely across studies (Figure 1). Heterogeneity was very large ($I^2 = 96.9\%$), and the 95% prediction interval, $[-.75, .25]$, was wide enough to include zero and weak positive values. This means that the pooled value should not be read as the expected correlation in every classroom. Differences in the anxiety scales, in the achievement measures (tests, report card grades or teacher-reported grades), and in the students sampled may all contribute (Table 2), but the present data do not allow us to say which of them explain the differences.

The subgroup analysis by school level suggested a stronger association in elementary samples ($r = -.44$, $k = 6$) than in middle school samples ($r = -.11$, $k = 2$) or in mixed-grade samples ($r = -.24$, $k = 2$). However, the difference between school levels was not statistically significant, $Q(2) = 4.84$, $p = .089$, the middle school estimate had a very wide interval, and the subgroups contained few studies. These results are exploratory, and we do not draw conclusions about why the association might differ by school level. Comparisons between passive and active control conditions did not apply to this correlational question. The sensitivity analysis, in which each study was removed in turn, gave pooled estimates between $-.39$ and $-.31$, so no single study determined the overall result. The Egger test did not indicate funnel plot asymmetry (intercept = -1.96 , $p = .680$), although a test with ten studies has little power.

For teachers of grades 1 to 9, the findings suggest paying attention to students' feelings about mathematics as well as to their scores. Students who look worried during mathematics lessons or tests may benefit from a calm classroom, clear explanations and chances to practise without pressure. At the same time, the data are correlational, so our results do not show that lowering anxiety will raise achievement, or that low achievement does not itself cause anxiety. Schools should therefore regard anxiety as one of several factors to watch, and should not rely on a single anxiety score to judge a student.

Conclusion

Across ten studies of students in primary and lower secondary schools, higher mathematics anxiety was associated with lower mathematics achievement, with a moderate pooled correlation of $r = -.34$. The association varied greatly between studies and may be stronger in elementary samples, although this difference was not statistically significant. Because the evidence is correlational, small in number and automatically extracted, teachers can

use it as a reason to attend to students' anxiety, but it does not show that reducing anxiety will by itself raise achievement.

This synthesis has several limitations. Only ten studies were included, and some had small samples (Balakonda, 2025) while others were large (Carey et al., 2017). The studies came from different countries and used different anxiety scales and different achievement measures, which makes the combined estimate a rough summary. Some samples mixed students from several grades (Carey et al., 2017; Reali et al., 2016), and one included students slightly older than the target range (Reali et al., 2016). Subgroups contained as few as two studies, so subgroup estimates are imprecise. All of the included studies were correlational, so the direction of any relationship cannot be established.

The studies were found with a limited search of open-access sources, and the data were extracted automatically from the full texts. Every extracted number was checked against the text, but a human did not review the extraction, and several candidate studies could not be included because their full texts or correlations were not available or could not be read reliably. Where a study reported correlations for several outcomes, we used the one for the main achievement measure, and this choice could affect the result. For these reasons, the findings should be treated as provisional.

In addition, screening and data extraction were automated with a language model, and extracted numbers were verified only by matching them against the full text. A number can be present in the text yet belong to a different group or measure. Only open-access studies whose full texts could be retrieved were included; subscription-only and unpublished studies were not.
